ABSTRACT

With four years of nearly-continuous photometry from Kepler, we are finally in a good position to apply asteroseismology to $\gamma$ Doradus stars. In particular several analyses have demonstrated the possibility to detect non-uniform period spacings, which have been predicted to be directly related to rotation. In the present work, we define a new seismic diagnostic for rotation in $\gamma$ Doradus stars that are too rapidly rotating to present rotational splittings. Based on the non-uniformity of their period spacings, we define the observable $\Sigma$ as the slope of the period spacing when plotted as a function of period. We provide a univoque relation between this observable $\Sigma$ and the internal rotation, which applies widely in the instability strip of $\gamma$ Doradus stars. We apply the diagnostic to a handful of stars observed by Kepler. Thanks to g-modes in $\gamma$ Doradus stars, we are now able to determine the internal rotation of stars on the lower main sequence, which is still not possible for Sun-like stars.

Key words: asteroseismology – stars: oscillations – stars: rotation – stars: interiors.

1 INTRODUCTION

With four years of nearly-continuous photometry from Kepler, we are finally in a good position to apply asteroseismology to $\gamma$ Doradus ($\gamma$ Dor) stars. These stars are late A- to early F-type stars, with masses ranging from about 1.3 to 2 $M_\odot$. They burn hydrogen in their convective cores, surrounded by a radiative region, where a shallow convective layer appears. Such shallow convective envelopes trigger gravity oscillation modes (g-modes) driven by the convective blocking mechanism (see Guzik et al. 2000; Dupret et al. 2005, and references therein). These modes probe the innermost regions and in particular the interface between convective and radiative layers. Therefore, $\gamma$ Dor stars are ideal for studying convective core physics. It is expected that phenomena such as transfer of angular momentum and mixing of chemical elements occur at the edge of convective cores, in the surrounding radiative regions (see for instance Kippenhahn & Weigert 1994). Whether it is caused by convective overshooting, shear induced turbulence or gravity waves is still matter of debate.

Another interesting motivation for $\gamma$ Dor stars seismology lies in the fact that their mass range overlaps with the masses of the red giant stars observed by the NASA Kepler space photometry mission. One of the most important developments in stellar physics that Kepler facilitated was the inference of the core rotation periods of red giant stars (Beck et al. 2012; Deheuvels et al. 2012). After 25 months of observation, from the seismic analysis of 1200 stars Mosser et al. (2012) measured the core rotation periods of 300 red giants, among which over one third have masses between 1.2 and 2 $M_\odot$. These were shown to be in disagreement with stellar evolution modelling (Eggenberger et al. 2012; Marques et al. 2013; Ceillier et al. 2013). Since then, a number of non-standard angular momentum transport processes have been implemented in stellar evolution models: transport by meridional circulation and shear induced turbulence (Eggenberger et al. 2012; Marques et al. 2013), transport by the Taylor-Spruit instability (Heger et al. 2005; Cantiello et al. 2014), by internal gravity waves ( Fuller et al. 2014) and transport by mixed modes (Belkacem et al. 2015). However the slow core rotation of red giant stars at the base of the red giant branch still remains unexplained by theory. For that reason, we lack knowledge of the inner rotation profile of low-to-intermediate mass stars on the main sequence (MS). The work presented here aims to address this. We establish a new method of measuring the core rotation periods of the intermediate-mass stars on the MS, specifically for $\gamma$ Doradus pulsators.

The g-modes in $\gamma$ Doradus stars typically have periods close to one day, which makes ground-based study exceedingly difficult. At first, the space missions such as MOST, CoRoT, and Kepler allowed to address the stability and hybridity of $\gamma$ Doradus stars (see for
instance Grigahcène et al. 2010; Hareret 2012; Zwintz et al. 2013; Uytterhoeven et al. 2011; Tkachenko et al. 2013). After four years of nearly-continuous data from Kepler, it is now possible to perform detailed asteroseismic studies of γ Dor stars based on their g-modes (see Bedding et al. 2015; Van Reeth et al. 2015). Among the Kepler stars with KIC temperatures between 6000 K and 10000 K, and log g values between 3.0 and 4.5, we have identified around 6000 A- early F-type stars. Approximately one thousand of these show excess power in the γ Dor g-modes frequency range.

Unlike for low-mass stars, in γ Dor stars the convective envelopes are too shallow to generate a magnetic field able to act as a magnetic torque and slow down their surfaces (Schatzman 1962). For that reason, these stars typically have projected rotation velocities of around 100 km s$^{-1}$ but that can reach up to 250 km s$^{-1}$ (see for instance Abt & Morrell 1995; Royer 2009).

When a star rotates, the degeneracy of the frequencies is lifted and a rotational splitting appears between modes of same radial order (n) and angular degree (ℓ) but different azimuthal order (m). If the star rotates slowly, the multiplet structure holds, and the splitting directly gives the average rotation rate in the cavity probed by the modes. This is possible thanks to a simple model of the effect of rotation as a first-order perturbation of oscillations, an approach derived by Ledoux (1951). Examples of measured rotation rates using that method can be found for instance in Kurtz et al. (2014), Súgata et al. (2015), Schmid et al. (2015), Keen et al. (2015), and Murphy et al. (2016). However most of Kepler’s γ Dor stars do not show clear multiplet structures. Also, if the rotation period is larger or of the same order of the pulsation period, the rotational splitting becomes difficult to determine and no longer provides an accurate measure of the internal rotation rate.

For moderately rotating stars, the traditional approximation of rotation (hereafter TAR, Eckart 1960), allows to account for rotation in the pulsation treatment. By making simplifying hypotheses, the TAR conserves the separability of the oscillation equations. In particular, it assumes the star is rotating uniformly. In that framework, Bouabid et al. (2013) showed the main features due to the effect of rotation on the seismic spectra of γ Dor stars. With the full four years of data from Kepler, Bedding et al. (2015) and Van Reeth et al. (2015) were able to identify such features in observations, opening the way to the seismic determination of rotation in γ Doradus stars.

Our choice here is to lift the assumption of uniform rotation, and the simplifying hypotheses which are implied in the TAR, in order to obtain pulsation spectra of g-modes in non-uniformly, rapidly rotating γ Dor stars, with the quality required for comparison with observations. To do so, we make use of the non-perturbative pulsation modelling method developed by Ouazzani et al. (2012, 2015). Hence, the formalism used here allows us to explore any kind of rotational profile, including rotational velocities close to the break-up velocity.

In Sect. 2 we give a brief description of the stellar models that have been explored in this study. In Sect. 3 we present the non-perturbative approach, as well as of the traditional approximation of rotation, and we provide an in-depth comparison of the two methods to estimate the validity of the traditional approximation. In Sect. 4, we describe the global effects of rotation on the g-mode pulsation spectra and then, more specifically, on the g-modes period spacings. That allows us to define a new seismic diagnostic tool: the slope of the period spacing as a function of the period. We explore the impact of different parameters (i.e. stellar parameters, metallicity, centrifugal distortion, type of mixing) on that new diagnosis tool in Sect. 5. Finally, we discuss and summarize the results and give an example of application in Sect. 6.

2 STELLAR MODELS

Stellar models were computed with the stellar evolution code CLES (Scuflaire et al. 2008a) for masses between 1.2 and 1.9 M$_\odot$, and with initial helium mass fraction Y = 0.27. We adopted the AGSS09 metal mixture (Asplund et al. 2009) and corresponding opacity tables obtained with OPAL opacities (Iglesias & Rogers 1996), completed at low temperature (log T $<$ 4.1) with Ferguson et al. (2005) opacity tables. We used the OPAL2001 equation of state (Rogers & Nayfonov 2002) and the nuclear reaction rates from NACRE compilation (Angulo et al. 1999), except for the $^{14}$N(p, γ)$^{15}$O nuclear reaction, for which we adopted the cross-section from Formigola et al. (2004). Surface boundary conditions at T = T$_{\text{eff}}$ were provided by ATLAS model atmospheres (Kurucz 1998). Convection was treated using the mixing-length theory (MLT) formalism (Böhm-Vitense 1958) with a parameter $\alpha_{\text{MLT}} = 1.70$.

We considered models with and without convective core overshooting (expressed in local pressure scaleheight, H$_{p}$), as well as with and without turbulent diffusion. Since the CLES code does not include effects of rotation on transport of angular momentum or chemical species, we instead introduced mixing by turbulent diffusion, following the approach of Miglio et al. (2008). This reproduces an effect of rotationally-induced mixing that is quite similar to overshooting, but in addition tends to smooth chemical composition gradients inside the star. In models including this type of mixing, the coefficient of turbulent diffusion was set to $D_t = 700 \text{cm}^2/\text{s}$ and kept constant to this value during evolution and in every layer of the models. This value was selected from a previous calibration to Geneva models with similar masses (Miglio et al. 2008).

A grid of stellar models was computed accordingly to these prescriptions, whose parameters are given in Table 2. We did not calculate pulsational stability, but we made sure that the grid maps the entire γ Doradus instability domain (Bouabid et al. 2013). Table 1 gives more details of the parameters of specific models used below for illustration purposes.

As explained by Miglio et al. (2008), if no specific mixing is added to models with growing convective cores (and therefore a chemical discontinuity) on the main sequence, a contradictory situation appears in regards to the convective criteria, leading to a semi-convective region. More generally, the stratification at the boundary of the convective core depends on the numerical treatment adopted. In our CLES version, we do not apply a specific treatment to these transition layers. Instead, a double mesh point is introduced at the boundary of the convective core in the models used for the computations of oscillations. This required modification of part of our pulsation codes, i.e. the implementation of matching conditions at interfaces between the convective core and the surrounding radiative region. This treatment is specially important for pulsational studies, to prevent numerical artefacts creating additional cavities trapping the g-modes.

3 OSCILLATION COMPUTATION METHODS

Rotation induces centrifugal and Coriolis forces which distort the star, i.e. the equilibrium structure is no longer spherical, and modify the spectrum of eigenfrequencies and eigenfunctions of the oscillation modes. In this article, we explore gravity and gravito-inertial pulsation modes of γ Doradus stars models. In rotating stars, these modes are often computed assuming simplifying hypotheses. This is the case with the traditional approximation of rotation (TAR, developed for geophysics by Eckart 1960, and applied to stellar pulsations)
by Berthomieu et al. (1978). It neglects the centrifugal distortion and part of the contributions of the Coriolis force. Another approach, adopted by Dintrans & Rieutord (2000); Lee & Baraffe (1995), is to fully account for the Coriolis force while neglecting the centrifugal distortion. The most complete approach accounts for both the Coriolis force and the full effect of the centrifugal force through a two-dimensional (2D) non-perturbative method as developed for polytropes by Reese et al. (2006), for non-polytropic-homogeneous models by Reese et al. (2009), and for distorted models of δ Scuti stars by Ouazzani et al. (2015). These three methods – i.e. TAR, complete one-dimensional (1D) and complete 2D – have been compared by Ballot et al. (2012) using polytropic models. According to them, the 1D non-perturbative approach – which presents the advantage of requiring less numerical resource – , and the TAR give satisfactory results compared to the full 2D approach. Throughout this study we therefore work with one-dimensional spherical stellar models. A further justification for this is given in Sect. 5.2. Moreover, in this article we have performed calculations with both the TAR and the non-perturbative approach. This section describes the two methods in more detail, and comparing them for spherical models of γ Doradus stars.

3.1 Non-perturbative Modelling

The oscillation modes were computed as the adiabatic response of the structure to small perturbations, i.e. of the density, pressure, gravitational potential, and velocity field. The ACOR code was developed for this purpose and is presented in Ouazzani et al. (2012). This oscillation code solves the hydrodynamics equations perturbed by Eulerian fluctuations, performing direct integration of the 2D problem. The numerical method is based on a spectral multidomain method which expands the angular dependence of eigenfunctions into spherical harmonics series, and whose radial treatment is particularly well adapted to the behaviour of equilibrium quantities in evolved models (at the interface of convective and radiative regions, and at the stellar surface). The radial differentiation scheme is made by means of a sophisticated finite difference method, which is accurate up to the fifth order in terms of the radial resolution (developed by Scuflaire et al. 2008b, for the LOSC adiabatic code). This code has been validated by comparison with the results of Reese et al. (2006) for polytropic models. The agreement between the two codes is excellent.

In this study, we have relied on the non-adiabatic stability calculations provided in Bouabid et al. (2013) in order to determine the range of radial orders to investigate. All the pulsations spectra presented here, whatever the method used, are calculated for radial orders between $n = -50$ to $-20$. Note that, by convention, g-modes radial orders are negative. With the non-perturbative approach in particular, we have calculated pulsation spectra of dipolar modes for all the models whose parameters are given in Tab. 1, and for quadrupolar modes for the models 1z, 2m and 3t, covering a range of uniform rotation frequencies, from zero to 23 µHz.

Here, the pulsation modes have been computed using up to 5 spherical harmonics, i.e. for a given $m$, $\ell = 1$ to 9 with odd value for dipolar modes, and $\ell = 2$ to 10 with even value for the quadrupolar ones. We have made sure, by the mean of convergence tests, that the frequencies do not vary significantly when adding a sixth spherical harmonic in the series. The resulting modes have multiple $\ell$ characters, they are then assigned an effective angular degree, taking the dominant contribution in the series.

3.2 The traditional approximation of rotation

In rotating stars, the equation system for pulsations is not separable in terms of the radial and horizontal coordinates, unlike for the case without rotation. The TAR is an approximate treatment that conserves the separability of the system. The first hypothesis is made on the rotation profile by assuming solid-body rotation. The centrifugal distortion is neglected and hence spherical symmetry is assumed. Furthermore, considering the properties of low frequency high order g-modes, the TAR neglects the Coriolis force associated with radial motion and radial component of the Coriolis force associated with horizontal motion. Practically, it consists of neglecting the horizontal component of the angular velocity so that $\Omega = [\Omega \cos \theta, 0, 0]$ in the spherical polar coordinates. Finally, the Cowling approximation is made (Cowling 1941), which neglects the perturbation of the gravitational potential. As a result, the motion equation for pulsations is separable in terms of the radius and latitude. It can be reduced to an equation for the radial component,

which is similar to the one without rotation, and a Laplace tidal equation for the horizontal component, whose eigenfunctions are the Hough functions. For a detailed derivation of these equation, we refer to Unno et al. (1989) Sect. 34.3, or Lee & Sato (1987).

This approximation has been implemented in the LOSC adiabatic and MAD non-adiabatic oscillation codes, the details of which have been given by Bouabid et al. (2013) and Salmon et al. (2014). In the non-adiabatic case, the TAR does not ensure the separability of the energy equation, so that further approximation must be made (as e.g. the one developed by Savonije et al. 1995, and used in Townsend 2005). In our version of the MAD code with TAR, we obtain the separability by replacing the \( \ell (\ell + 1) \) term by \( \lambda \) in the energy equation, with \( \lambda \) the eigenvalue of the Laplace tidal equation. This last assumption holds because horizontal radiative flux terms are small in the case of low degree g-modes as those of γ Dor analysed here.

We have computed a selection of spectra with this method, for the sake of comparison with the non-perturbative approach, for the models 1z, 2m, and 3m", and for the whole rotation frequency range from 0 to 23 \( \mu \)Hz.

### 3.3 Asymptotic formulation of the TAR

Under the TAR approximation, the simplification of the problem allows for an asymptotic formulation derived from the Tassoul (1980) formula for g-modes periods, where \( \ell (\ell + 1) \) is replaced by \( \lambda \). This eigenvalue depends on \( \ell, m \) and the spin parameter \( s = 2\nu_{rot}/\nu_{co} \), \( \nu_{co} \) being the frequency of the mode in the corotating frame. For the sake of clarity we will use hereafter \( \Delta \nu_{f,m,n}(\lambda) \), with \( n \) the radial order of the mode. The asymptotic formula is then given by:

\[
P_{co}(n) = \frac{2\pi^2 (n + \frac{1}{2})}{\sqrt{\Delta f_{m,n}(s) \int_{r_0}^{r_1} N dr}}.
\]

where \( r_0 \) and \( r_1 \) are the limits of the g-modes cavity, determined by \( \omega^2 < N^2, S^2 \), i.e. for an angular frequency squared smaller than both the square of the Brunt-Väisälä \( (N) \) frequency, and the square of the Lamb frequency \( (S) \). The period spacing, given as the difference between the periods of two modes of same angular degree, same azimuthal order, and consequent radial orders, after some calculations (see Appendix A of Bouabid et al. 2013), can be expressed as follows:

\[
\langle \Delta P_{co} \rangle \approx \frac{2\pi^2}{\sqrt{\Delta f_{m,n}(s+1) \int_{r_0}^{r_1} N dr}} \left( 1 + \frac{1}{2} \frac{d\nu_{rot}}{d\ln r} \right).
\]

Note that the period appears in both terms (hidden in the spin parameter \( s \)) of these equations in non-linear terms, the periods and period spacings are therefore obtained using an iterative scheme. Initial guesses of the periods were obtained by taking the adiabatic periods obtained in the case without rotation (low numerical cost) as input. The equation was then solved with the Van Wijngaarden-Dekker-Brent iterative scheme, which is a refined bisection method (Press et al. 1996).

The asymptotic formulation requires very little computational resources and time, which is an clear advantage compared to the aforementioned methods. For that reason, it is used in this study for a wide exploration of the HR diagram (see Sect. 5.1). However, we first investigate its domain of validity by comparing with the non-perturbative method and the TAR.

![Figure 1. Top: Mean period spacing for modes with radial orders ranging from \( n = -20 \) to \( n = +50 \), computed with the non-perturbative method (ACOR, black), the traditional approximation (TAR, blue), and the Asymptotic formula derived from the traditional approximation (Asymptotic, red), for model 1z given in Tab. 1. Bottom: relative discrepancies with respect to the non-perturbative calculations for the TAR (blue), and for the Asymptotic formulation (red). A new asteroseismic diagnostic for rotation in γ Doradus stars

4 EFFECT OF ROTATION ON G-MODES

4.1 Global effect on the spectrum

Here we explore the global effects of rotation on the frequency spectrum. We aim to give some insights for interpretation of observed pulsation spectra, giving the main indicators in terms of observables.

Even in the co-rotating frame, and even when neglecting the distortion due to the centrifugal force, the degeneracy of pulsation modes is lifted, and the rotational splitting of frequencies appears. As the rotation rate increases, three rotation regimes can be identified. The classification of these regimes depends on the magnitude of the rotational splitting of frequencies. In the asymptotic method, the error on the mean period spacing is considerable: 15% for the asymptotic values. This corresponds to a discrepancy of 2600 s for model 2m and 3 m.

For comparison between the three methods, we investigated the value of the mean period spacing. In the asymptotic method, it is directly given by Eq. 2, whereas for the TAR and the non-perturbative approach, it is simply the average of the period spacings over the eigenmodes with radial orders between –50 and 20. Figure 1 gives the mean period spacing as a function of the uniform rotation frequency computed with the three methods in the top panel. The largest discrepancies arise for the retrograde modes (solid lines), whereas the zonal and prograde modes agree well. In the bottom panel, we give the discrepancy of the TAR and of its asymptotic formula, relative to ACOR. For retrograde modes, the error on the mean period spacing is considerable: 15% for the asymptotic values. This corresponds to a discrepancy of 2600 s (0.03 days) with the TAR and 4300 s (0.05 days) with the asymptotic formula for a value of the mean period spacing around 17 000 s (0.2 days). However, it seems that, for any azimuthal order, the TAR is giving values that are in mean period spacing around 17 000 s (0.2 days). However, it seems 4300 s (0.05 days) with the asymptotic formula for a value of the mean period spacing.

The worst case arises for retrograde modes. The impact of the number of spherical harmonics included in the pulsation modelling has been investigated, and can be excluded as sources for these discrepancies. As mentioned in Ballot et al. (2012), this is probably due to the fact that the retrograde modes fall into the gravito-inertial regime when rotation exceeds a critical value. It is well known that the gravito-inertial regime is reached when the period of modes in the co-rotating framework is higher than \( P_{\text{rot}} = P_{\text{m}}/2 \). When rotation increases, for a given radial order, a retrograde mode is shifted towards higher frequencies. Therefore, this regime is reached for retrograde modes at lower rotation rates than for prograde modes, which are shifted towards lower periods.

For rapid rotation, \( \delta \nu_m / (\Delta P / P^2) \gg 1 \), the structure of the frequency spectrum changes radically. The prograde modes are shifted towards higher frequency, whereas the retrogrades are shifted towards lower frequencies, to such an extent that they appear in the frequency spectrum as clusters of modes, each with a given angular degree and azimuthal order and varying radial order (see Fig. 2, right and Van Reeth et al. 2015 for such features in Kepler observations).
The mean value depends on the sharpness of the core. In that case, the period spacing rather oscillates around a constant value, but around a linear trend, that, in the inertial frame of the observer, is decreasing for prograde and zonal modes, and mainly increasing for retrograde modes. As the rotation increases (in Fig. 3, from no rotation in blue, to 7 μHz, i.e. 0.6 c/d, in black, and then 15 μHz, i.e. 1.3 c/d, in red), the slope of the linear trend decreases strongly for prograde modes, less strongly for the zonal modes, and increases for the retrograde ones. In comparison to Bouabid et al. (2013), these rotation periods correspond to Ω/Ωc = 0, 0.32, and 0.68, with Ωc = √8GM/27R3 being the critical break-up velocity defined by the Roche model. Additionally, in the inertial frame, the pattern of the variation varies with the period. More precisely, for retrograde modes, the cycle length of the period spacing oscillation increases with period, whereas it decreases for the zonal and retrograde modes. Nevertheless, the number of modes in the pattern, uniquely related to the location of the Ψμ(see Miglio et al. 2008, for an elegant demonstration), remains constant.

To sum up, the effect of rotation is two-fold. On the one hand the cycle length of the oscillation in period spacing varies, and on the other hand, the period spacing shows a global linear trend. The slope of this trend depends on the angular degree and azimuthal order, so that:
\[ \Delta P_{n,ℓ,m} = \Sigma_{ℓ,m} P_{n,ℓ,m} + r_{ℓ,m}. \]  
(3)
where \( \Delta P_{n,ℓ,m} \) is the period spacing, \( P_{n,ℓ,m} \) the modes period, and \( \Sigma_{ℓ,m} \) is the slope. In the following section (Sect. 5), we explore how \( \Sigma_{ℓ,m} \) varies with different physical parameters, starting with its dependency on the rotation rate.

### 4.3 The slope Σ as a diagnostic of rotation

In order to explore the dependency of Σ on rotation, we performed a series of tests on three different stellar models: 1z, a 1.4 M⊙ model on the ZAMS (Zero Age Main Sequence); 2m, a 1.6 M⊙ model on the MS; and 3t, a 1.86 M⊙ model on the TAM (Terminal Age Main Sequence, see Table 1), which cover the Φ Doradus instability strip. For the sake of simplicity, we opted for the models with diffusive transport. The impact of stratification at the edge of the convective core is explored in Sect. 5.3. For each stellar model, we have computed the pulsation spectra corresponding to uniform rotation frequencies ranging from 0 to 23 μHz (i.e. 0.5 to 5 days in period).

For each pulsation spectrum, we made a linear fit to the period spacing ΔP as a function of period (such ΔP versus P diagrams are shown Fig. 3). The slope \( \Sigma_{ℓ,m} \) measured from that linear fit is plotted against the corresponding rotation frequency in Fig. 4 for dipolar (left) and quadrupolar (right) modes. We see that the behavior of \( \Sigma_{ℓ,m} \) as a function of the rotation frequency is very similar for the three stellar models that have been explored. Hence, given the differences between those models in terms of internal structure (evolutionary stage, extension of convective and radiative regions, etc., see Tab. 1), the slope \( \Sigma_{ℓ,m} \) does not depend on the internal structure. It seems to depend solely on the mode angular degree and azimuthal order \{ℓ, m\}, and on the rotation rate of the model. For the sectorial retrograde modes \{ℓ = 2, m = 2\}, the slope \( \Sigma_{ℓ,m} \) has been plotted only up to 11 μHz because at higher

Figure 3. Period spacing as a function of the period for dipolar (ℓ = 1) retrograde (m = +1, top), zonal (m = 0, middle), and prograde (m = −1, bottom) modes, for different rotation rates: in blue without rotation, in black with a rotation frequency of 7 μHz (0.6 c/d), and in red with a rotation of 15 μHz (1.3 c/d). In dotted lines are given the period spacings computed with the TAR.

Note that this frequency grouping due to rapid rotation has been found also in a Be stars observed by MOST (Cameron et al. 2008).
A new asteroseismic diagnostic for rotation in γ Doradus stars

rotation frequencies, their frequency reaches negative values in the inertial frame, which results in frequencies reflected around zero, therefore obeying a different dynamics (as found also in Bouabid et al. 2013).

The great advantage of Σ is that, except for retrograde modes, it does not depend on the radial orders excited and detected, contrary to the mean period spacing. Here we have considered g-modes with radial orders n from -50 to -20, and we have verified that Σ does not vary when the radial order range is truncated for prograde and zonal modes. The case of retrograde modes is more problematic, Sect. 6.2 is dedicated to this issue.

To sum up, modes in rapidly rotating γ Doradus stars tend to cluster in groups of modes of given \{ℓ, m\}, and the period spacings of these groups of modes follow a linear trend with a slope directly related to the rotation rate. As such, the slope Σℓ,m constitutes a promising seismic diagnostic for rotation in γ Doradus stars.

5 SENSITIVITY OF THE SLOPE Σ

In the previous section, we have shown that the slope Σ of the period spacing as a function of the period seems to depend strongly on the rotation period of the model. We considered three different stellar models of γ Doradus stars, in three evolutionary stages of their main sequence. In this section, we further investigate this rotation-slope relation, and the impact of a changing stellar structure on that relation.

5.1 Sensitivity to the stellar parameters and the metallicity

In order to study the changes in the slope Σℓ,m for varying stellar parameters, we computed the g-modes spectra for the grid of models given in Table 2, restricting ourselves to the case with turbulent diffusion and no overshoot, but making use of the asymptotic formulation accounting for rotation. As shown in Sect. 3.4, the validity of the asymptotic formulation is limited. However, it is used here because it allows us to thoroughly explore the γ Doradus instability strip which would be numerically significantly more expensive with the TAR or with the complete method. Hence, this approach allows us to assess the variation of the slope when varying the stellar parameters, not its absolute value, which can be erroneous due to the limited validity of the asymptotic method.

Figure 5 (left) gives the slope Σ (in colour scale) for dipolar prograde modes in the grid of models given in Tab. 2, with turbulent diffusion \( D_t = 700 \text{ cm}^2 \text{s}^{-1} \) and no overshoot, for a rotation frequency of 7 \( \mu \text{Hz} \), and a metallicity \( Z = 0.014 \). We refer to Fig. 11, Fig. 12 and Fig. 13 at the end of the article for a full overview for dipolar modes (prograde, zonal and retrograde modes resp.), for two different rotation frequencies (7 \( \mu \text{Hz} \) and 15 \( \mu \text{Hz} \)), and three different metallicities. Also in these figures, we report on the mean and standard deviation of \( \Sigma ℓ,m \) at a given rotation period, and for a set of quantum numbers \{ℓ, m\}.

The first striking feature is the uniformity of the values for the prograde modes, for the zonal modes, as well as for the retrograde modes at the lowest rotation period. For these, mostly the low-mass end of the main sequence in the HR diagram seems to depart significantly from the uniform slope value by two sigma. The low end of the mass range corresponds to the mass limit for the disappearance of the convective core. Therefore, this variation at the low-mass end of the instability strip is due to the drastic differences of internal structure between radiative cores models (with masses ranging approximately from 1.2 to 1.3 \( \text{M}_\odot \)) and convective core models everywhere else. To illustrate this point, the size of convective cores in the models covering the instability strip is plotted in Fig. 5 (right).

The dark blue points are models that do not manage to sustain a convective core when they leave the ZAMS. This hypothesis is supported by the fact that the slope is closer to the mean value at the beginning of the main sequence, i.e. when the star has developed a convective core, and the discrepancy appears progressively when the core can no longer sustain convection.

The metallicity does not affect the slope in most of the instability strip, except again in the low-mass end (as illustrated in Fig. 11 and Fig. 12). Note that when the metallicity increases, the variation seems to increase and to extend in mass. This is particularly obvious...
for the dipolar prograde modes, for a rotation of 7 \(\mu\)Hz (Fig. 11, left). This confirms the fact that the origin of the variation is likely due to the absence of a convective core, given the appearance of a convective core occurs at higher masses with increasing metallicity. Note that at a given rotation period, this effect is higher for prograde modes than for zonal modes, and in turn higher for zonal modes than for retrograde modes. An exploration of the kernels of modes of different azimuthal orders at a given radial order showed that prograde modes probe deeper layers than zonal and retrograde modes. This confirms the conclusion that the variation is due to the appearance of a convective core, and is all the more important for the modes which probe closer to the core.

Apart from these local variations in the low-mass end of the HR diagram, the slope \(\Sigma\) varies very little with the stellar mass, evolutionary status (along the main sequence) or metallicity. The mean values agree within the standard deviation regardless of the value of the metallicity, and are identical in most cases. The standard deviations themselves are typically one order of magnitude lower than the mean value, and vary from \(4\%\) in the best case (zonal modes at 15 \(\mu\)Hz of rotation) to \(18\%\) in the worst (for the zonal modes with 7 \(\mu\)Hz of rotation frequency). The behaviour of retrograde modes will be discussed further in Sect. 6.

### 5.2 Impact of the centrifugal distortion

In order to assess the influence of centrifugal distortion on g-mode spectra in \(\gamma\) Dor stars, we compared pulsations computed for a spherical model with those computed for an equivalent model, distorted a posteriori. The spherical model is labelled \(3m'\) in Table 1, with a differential rotation profile, i.e. a convective core which rotates at around 15 \(\mu\)Hz (1.3 c/d), and an envelope at a rate of 7 \(\mu\)Hz (0.6 c/d). The 2-dimensional model was built following the method developed by Roxburgh (2006). It consists of building the 2D acoustic structure of a rotating star in hydrostatic equilibrium, starting with spherical profiles of the structural quantities, and including the centrifugal force, using an iterative scheme. The pulsations of both models were calculated using the ACOR code. For the 2-dimensional model, we used the 2D integration scheme which has been adapted to handle non-barotropic models of stars (for more details, see Ouazzani et al. 2015). The dipolar modes spectra were computed using 5 spherical harmonics in both schemes. In Fig. 6 we show the period spacing of dipolar g-modes plotted against the period. Although the periods and the period spacings of individual modes seem to differ significantly, as shown in Fig. 6, the global characteristics are conserved: the mean value of the period spacing, the number of modes per pattern, the extent of the pattern in period and, particularly, the slope \(\Sigma_{\ell, m}\) for each group of modes of same azimuthal order. The slopes obtained in the pulsation spectra for the spherical and the distorted models are given in Tab. 3. Note that we do not find higher deviations for the retrograde modes than for the prograde ones. However, the error in slope induced by spherical modelling of the structure is of the same order as the dispersion due to changing stellar parameters or mixing (next section). Additionally, the intense computational resources required by the 2D calculations prevent a global seismic approach at this stage. We will therefore consider spherical modelling for the remainder of this paper.

### 5.3 Effect of the diffusive or instantaneous mixing

To infer the effect of the stratification at the edge of the core, we investigated the g-mode period spacings of three models located close to each other in the HR diagram (see Fig. 7, top), but with three different mixing scenarios. The model \(3m'\) was computed without any mixing (see Tab.1, and in black in Fig.7), the model \(3m\) presents diffusive mixing with a coefficient \(D_t = 700\text{cm}^2\text{s}^{-1}\) (Fig.7 in blue), and model \(3m''\) includes overshooting over 0.2 local pressure
A new asteroseismic diagnostic for rotation in γ Doradus stars

Figure 6. Period spacings of dipolar modes as a function of the period for model 3m’. The red curves refer to the distorted model and the grey curves to the corresponding spherical model.

Figure 7. Top: Hertzsprung-Russell Diagram where the three models considered here are shown (Table 1), together with the evolutionary tracks they belong to. Middle: Hydrogen profile of the three models. Bottom: Square of the Brunt-Väisälä frequency scaled by the Keplerian angular velocity, as a function of the fractional radius. The three models are 1.86 M\(_{\odot}\), with different stratification at the edge of the convective core: either with turbulent diffusion (3m, blue) or overshooting (3m”, black) or none (3m’, red).

scale heights (Fig. 7 in red). Note, from the HR diagram (Fig. 7, top) that switching on mixing at the convective core boundary, by extending the mixed region, results into a longer core-hydrogen burning phase.

In Fig. 7 (Middle) we give the hydrogen profile of the three models. As illustrated, the effect of turbulent diffusion is to smooth out the composition gradient without changing its position, whereas the convective core overshoot moves the location of the discontinuity, without impacting the gradient as such.

To understand the effect on pulsations, we plot the Brunt-Väisälä frequency profiles (bottom), which is the buoyancy frequency under which the g-modes are trapped. Since the mixing changes the location or the sharpness of the gradient of mean molecular weight, it changes the profile of \(N^2\), and therefore g-modes cavity.

The pulsation spectra of these models were computed with the non-perturbative method (Sect. 3.1), for \(\ell = 1\) modes with radial orders varying from -50 to -20. As illustrated in Fig. 8, period spacings show various behaviour: a steep molecular-weight gradient (such as in models 3m’ and 3m”, red and black resp.), results in a periodic pattern in the period spacing. The periodicity of this behaviour varies with the location of the mixed region boundary (Miglio et al. 2008), the closer the boundary is to the center, the higher the number of modes per pattern. In the presence of diffusive mixing (model 3m, blue), the period spacing shows a smooth behaviour. The aim here is to assess whether this has an impact on the value of the slope \(\Sigma\). In Tab. 4 the values of \(\Sigma\) for the three different mixing cases and for two rotation periods (corresponding to Fig. 8) are given. We compare the spread in \(\Sigma\) due to different mixing scenarios with the spread due to varying mass and evolutionary stage given in Fig. 11, Fig. 12 and Fig. 13. Once again, apart from the retrograde modes (which show a spread of 0.005 in slope), it seems that for the prograde and zonal modes, this spread is of the same order than the dispersion with mass and age (around 0.003). Therefore, we conclude that the mixing at the edge of the convective core does not impact the slope \(\Sigma\) of the period spacing of prograde and zonal modes significantly.

6 RESULTS AND DISCUSSION

In the previous section we have explored the dependency of the parameter \(\Sigma\) which is the slope of the period spacing as a function of the period. Here we try to draw a unique relation between this slope and the internal rotation frequency.
Figure 8. Period spacing as a function of the period of the dipolar modes computed for the models either with turbulent diffusion (3m, blue) or overshooting (3m', black) or none (3m', red) listed in Tab.1, together with linear fits, for uniform rotations of 1.65 days (left) and 0.77 days (right).

6.1 A univoque $\Sigma - \nu_{\text{rot}}$ relation

We evaluate the scatter caused by the differences in structure encountered in the $\gamma$ Dor instability strip. As mentioned in Sect. 5.1, the asymptotic formulation of the TAR is convenient to determine scatter, even if the absolute values can differ from the non-perturbative calculations. Hence, the strategy is to define the slope-rotation relation by averaging between the values for the models 1z, 2m and 3t. For each rotation frequency, the scatter in slope $\Sigma$ was computed using the asymptotic formula for the grid of models given in Tab. 2. The result is given in Fig. 9, for dipolar modes. This figure shows that there is a univoque relation between the slope of the period spacing as a function of the period and the internal rotation frequency in $\gamma$ Doradus stars. This relation shows that the observable $\Sigma$ could be used as a diagnostic for the rotation frequency in the same way that rotational splitting is used in the slowly rotating case. Note that the relation presented in Fig. 9 is valid for dipolar modes. Similarly, it is possible to establish a $\Sigma$-rotation relation for quadrupolar modes, as shown in the right panel of Fig. 4.
6.2 The case of retrograde modes

Once again, the largest spread is obtained for the retrograde modes. In the inertial frame, the impact of rotation on gravity modes is two fold: (i) the intrinsic effect of rotation on modes dynamics (mainly through the Coriolis force, but also through the centrifugal force), and (ii) the change of reference from the corotating frame to the inertial one. The zonal modes are not affected by the change of reference frame, but prograde and retrograde modes are shifted towards higher and lower frequency respectively. Depending on the sign of the azimuthal order, this either adds to (for prograde modes) or subtracts from (for retrograde modes) the intrinsic effect of rotation. The specificity of retrograde mode period spacing in the inertial frame comes from the competition between the two effects. The parameter which determines the domain of prevalence of these two effects is the spin parameter \( s = \frac{2\nu_{\text{rot}}}{\nu_{\text{co}}}, \) where \( \nu_{\text{co}} \) is the pulsation frequency in the co-rotating frame. At low \( s, \) the change of frame prevails, whereas the intrinsic effect takes over at high \( s. \) As a result, the prevailing factor can vary within one sequence of modes of same \( \ell, m \). This is seen in the upper panel of Fig. 3: the behaviour at 7 \( \mu \)Hz is dominated by the change of frame, whereas at 15 \( \mu \)Hz, the high period part of the spectrum starts to follow a different dynamics from the low period part, due to the prevailing Coriolis effect. As a consequence, describing the behaviour of the period spacing as a function of the period using a linear fit is less adequate for retrograde modes than for the zonal and prograde modes. Moreover, because the spin parameter depends on the period of modes, the transition between the two regimes can vary significantly from one stellar model of the grid to another. That explains why the spread in linear slope is much higher for retrograde modes than for zonal or prograde modes. Therefore, should the diagnostic given in Fig. 9 be used on observations of retrograde modes, we would recommend a more detailed modelling accounting for the period range on which the parameter \( \Sigma \) is determined.

Note that this could be treated more easily in the co-rotating frame. However, analyses in the inertial frame are needed to relate to seismic observables, which are measured in the inertial frame.

In addition, it is relevant to work in the inertial frame in the case of differential rotation, because the change of frame is not straightforward.

6.3 Application to observations

As a proof of concept, we use four stars observed by Kepler, one of which (KIC 4253413) was previously presented in Bedding et al. (2015). These stars have been observed quasi-continuously by the Kepler spacecraft for 18 (KIC 4253413, and KIC 6762992), 17 quarters (KIC 5476299), and 15 quarters (KIC 4177905) respectively. The measured oscillation periods shown in the period spacing versus period diagram Fig. 10 were extracted through the classical pre-whitening procedure using Period04 (Lenz & Breger 2005).

In order to apply the diagnostics based on the slope of the period spacing sequence, \( \Sigma, \) it is necessary to identify the angular degree and azimuthal order associated to an observed sequence of g-modes. To do so, we rely on the combined knowledge of the mean value of the period spacing, of the slope \( \Sigma, \) and of the range of observed periods. The mean value of the period spacing mainly carries information on the angular degree \( \ell. \) As seen in Fig. 1, it can be drastically changed by rotation, therefore a firm identification requires the knowledge of the other observables. As seen in Fig. 9, when negative \( \Sigma \) is found, there is a need to distinguish between zonal and prograde modes. An easy case arises when we deal with dipolar modes, with steep slopes (i.e. \( \Sigma \) values lower than \( 0.02 \) Hz).
-0.025), because only prograde modes can reach these values. In that case, one should rely on the range of observed modes. The shift in frequency prograde and retrograde modes undergo depends on rotation, and should be consistent with the value of $\Sigma$.

Hence, based on the range of periods, the period spacings in the range of observed periods, and the slope of the period spacing, the three sequences of modes could unambiguously be identified as dipolar prograde modes. Indeed, the slopes for all the stars are too steep to be attributed to zonal or retrograde modes, and the mean value of the period spacings are not compatible with modes of higher degree $\ell$. The slopes of the period spacing as a function of the period spacing was determined using a simple linear fit of the data points. The diagram given in Fig. 9 was then used in order to determine the rotation frequency as a well as the respective uncertainty. The latter is due to our lack of additional constraint on the star’s structure, i.e. stellar parameters and internal physics. A refined approach with tailored modelling in a star by star approach would help reducing this uncertainty, but this is out of the scope of this paper.

### 6.4 Conclusion

Based on the non uniformity of the period spacings of $\gamma$ Doradus stars, we defined a new observable $\Sigma$, the slope of the period spacing when plotted as a function of period. After a series of tests, we showed that this observable is uniquely related to the internal rotation. In this study, we have assumed a uniform rotation, the case of differential rotation will be investigated in a forthcoming paper. The relation between $\Sigma$ and the internal rotation applies widely on the main-sequence part of the instability strip of $\gamma$ Doradus stars. As a proof of concept, we apply the new asteroseismic diagnostic to a handful of $\gamma$ Doradus stars observed by Kepler. Using the g-modes observed in these stars, we are able to measure the internal rotation on the lower main sequence, which is still not possible in Sun-like stars. Combined with the core rotation rates determined in red giant stars (see Mosser et al. 2012, and references therein), these measurements will provide stringent constraints on angular momentum transport along the evolution of low-mass stars. The method presented here will allow one to retrieve internal rotation rates for a large sample of stars, which is particularly relevant in the context of the upcoming space missions TESS, and PLATO.

### ACKNOWLEDGEMENTS

The authors would like to thank Marc-Antoine Dupret and Josefiná Montalbán for fruitful discussions, and Jørgen Christensen-Dalsgaard for careful reading. Funding for the Stellar Astrophysics Centre is provided by The Danish National Research Foundation. The research is supported by the ASTERISK project (ASTERoseismic Investigations with SONG and Kepler) funded by the European Research Council (Grant agreement no.: 267864).
