ABSTRACT
We report spectroscopic observations for 19 δ Sct candidates observed by the Kepler satellite both in long and short cadence mode. For all these stars, by using spectral synthesis, we derive the effective temperature, the surface gravity and the projected rotational velocity. An equivalent spectral type classification has been also performed for all stars in the sample. These determinations are fundamental for modelling the frequency spectra that will be extracted from the Kepler data for asteroseismic inference. For all the 19 stars, we present also periodograms obtained from Kepler data. We find that all stars show peaks in both low- (γ Dor; g mode) and high-frequency (δ Sct; p mode) regions. Using the amplitudes and considering 5 c/d as a boundary frequency, we classified 3 stars as pure γ Dor, 4 as γ Dor - δ Sct hybrid, 5 as δ Sct - γ Dor hybrid, and 6 as pure δ Sct. The only exception is the star KIC 05296877 which we suggest could be a binary.

Key words: Stars: fundamental parameters – Stars: oscillations (including pulsations) – Stars: early-type

1 INTRODUCTION
Stellar pulsations offer a unique opportunity to constrain the intrinsic parameters of stars and, by using asteroseismology, to unveil their inner structure. In particular, the classical δ Sct variables are late A-type and early F-type stars that populate the instability strip between the age main sequence and terminal age main sequence, with 0.8 < M<sub>V</sub> ≤ 0.5 and pulsation periods ranging from about 20 min to 8 h (see Breger 2000, for a review). δ Sct stars pulsate in both radial and non-radial p modes and g modes, driven by the κ-mechanism, in particular in the He II ionization zone. The γ Dor variables, with periods between about 0.3 and 3 d, are mostly located near the cool edge of the δ Sct instability strip (Kaye et al. 1999). Their pulsations are driven by convective blocking at the base of their envelope convection zone (Guzik et al. 2000; Dupret et al. 2004; Grigahcène et al. 2004). The distinction between the two classes is clearer if we consider the value of the pulsation constant, Q (Handler & Shobbrook 2002). However, the location of the γ Dor stars in the Hertzsprung-Russell (HR) diagram suggests some relationship with the δ Sct variables. Indeed,
stars exist which show simultaneously both δ Sct and γ Dor pulsations (Henry & Fekel 2005; King et al. 2006; Rowe et al. 2006; Uytterhoeven et al. 2008a; Handler 2009). These hybrid objects are in principle of great interest, because they offer additional constraints on stellar structure. Indeed, the γ Dor stars pulsate in g modes which have high amplitudes deep in the star and allow us to probe the stellar core, while the p modes, efficient in deep in the star and allow us to probe the stellar core, while the p modes, efficient in

\[ \delta \text{Sct} \] and γ Dor domains, respectively. Many of these objects show periodograms with frequen-

\[ \gamma \text{Sct} \] – δ Dor oscillations be-

\[ \delta \text{Sct\,or\,} \gamma \text{Dor stars. The long-cadence data are not available in pure δ Sct stars, which may be liquid, by the transit method (Borucki et al. 1997). To accomplish this goal, Kepler is capable of measuring the stellar brightnesses to µmag precision (Gilliland et al. 2010) which, together with the long duration of the observations, make the data ideal for asteroseismology. Most of the observations are long-cadence (29.4-min) exposures, though a small allocation is available for short-cadence (1-min) exposures. The long-cadence as well as some short-cadence data released to the Kepler Asteroseismic Science Consortium (KASC) have been surveyed for δ Sct and/or γ Dor stars. The long-cadence data are not always suitable for a detailed study of δ Sct oscillations because many of these stars have frequencies higher than the Nyquist frequency (24.5 c/d) for 29.4-min sampling. These data are, however, suitable for the detection of δ Sct – γ Dor hybrids.

The early KASC data releases led to the discovery of the nineteen candidate δ Sct stars listed in Table 1; many more have been found in subsequent data releases, and ground-based studies of these stars are now in progress. Interestingly, many objects show periodograms with frequencies both in the p mode δ Sct and g mode γ Dor domains, i.e., they are candidate hybrid pulsators (Grigahcène et al. 2010). Dedicated short-cadence Kepler data for the most

promising hybrid candidates will be exploited for seismic studies of these stars. To this end it is extremely important to constrain the fundamental parameters of the stars (effective temperature $T_{\text{eff}}$, surface gravity $\log g$, projected rotational velocity $v \sin i$, luminosity $L/L_\odot$) in order to limit the range of models. Measurement of $v \sin i$ is essential to constrain the rotational velocity of the models. Stellar fundamental parameters can be obtained by using photometry, e.g., in the Strömgren system, or by means of mid- or high-resolution spectroscopic observations. Very few of the 19 Kepler δ Sct stars have previously been observed spectroscopically and no reliable estimates of the stellar parameters can be derived from the existing data. For this reason, we undertook a systematic spectroscopic study of these Kepler targets and report our results here. This work fits in the ground-based observational efforts of KASC with the aim to characterize all Kepler pulsators (Uytterhoeven et al. 2010a,b).

2 OBSERVATIONS AND DATA REDUCTION

The spectra used in our analysis were acquired with two different instruments:

(i) Loiano Observatory: We used the Bologna Faint Object Spectrograph & Camera (BFOSC) instrument attached to the 1.5-m Loiano telescope\(^2\). We adopted the echelle configuration with Grism #9 and #10 (as cross dispersers). The typical resolution was $R \sim 5000$. Spectra were recorded on a back-illuminated (EEV) CCD with $1300 \times 1300$ pixels of $20 \mu\text{m}$ size, typical readout noise of $1.73\ e^{-}$ and gain of $2.1\ e^{-}/\text{ADU}$. Observations were carried out during the nights of 2009 September 8 – 11. The exposure times ranged from 1200 to 3600 s for the brightest and faintest targets respectively.

(ii) INAF-OACT: the 91-cm telescope of the Istituto Nazionale di Astrofisica – Osservatorio Astrofisico di Cata-nia (INAF–OACT) was used to carry out spectroscopy of eight of the targets. The telescope is fibre linked to a R EOSC\(^3\) echelle spectrograph, giving $R \sim 20000$ spectra in the range 4300 – 6800 Å. The resolving power was checked using the Th-Ar calibration lamp. Spectra were recorded on a thinned, back-illuminated (SITE) CCD with $1024 \times 1024$ pixels of $24 \mu\text{m}$ size. The typical readout noise was $6.5\ e^{-}$ at a gain of $2.5\ e^{-}/\text{ADU}$. Observations were carried out during five nights: 2009 September 28, 29, 30 and November 19 and 28. Exposure times were fixed for all the stars at 1 h.

The reduction of spectra, which included the subtraction of the bias frame, trimming, correcting for the flat-field and the scattered light, the extraction of the orders, and the wavelength calibration, was done by using the NOAO/IRAF package\(^4\). The amount of scattered light correction was about 10 ADU. The S/N ratio of the spectra was at least $\sim 130$ and 80 for Loiano and OACT observatories, respectively.

3 PHYSICAL PARAMETERS

3.1 Parameters from photometry: $T_{\text{eff}}$ and $\log g$

Complete Strömgren-Crawford $uvby\beta$ photometry is available for seven objects in our sample (stars with an “a” in column 5 of Table 1) while $uvby$ data are present for three additional objects (stars with a “b” in column 5 of Table 1). The source of both the Strömgren and Strömgren-Crawford data is Hau & Mermilliod (1998). For the other six objects (identified with a “c” in column 5 of Table 1) plus the three stars in NGC 6866, only Johnson photometry is available, mainly in $BV$ filters. For these stars we used the values reported by SIMBAD. In the near-infrared, $JHK$ photometry of good quality is present in the 2MASS catalogue (Skrutskie et al. 1996) for all the targets.

For the seven stars with $uvby\beta$ photometry, $E(b-y)$ can be estimated by using the calibration by Moon (1985), using the IDL code UVBRETA. The result is reported in Table 1, where we have used the transformation $E(B-V) = 1.4\ E(b-y)$ (Cardelli et al. 1989). For the three stars without $\beta$ indices we used the equivalent spectral type derived in Section 3.2 to derive the intrinsic $E(b-y)$ from the relation between $E(b-y)$ and spectral type (Voigt 2006). Similarly, for five stars with $E(B-V)$ colours, we adopted the intrinsic $E(B-V)$ colours as a function of spectral type (Schmidt-Kaler 1982). We assigned a larger error to these values than those based on $uvby\beta$ photometry. The remaining four variables are cluster members, three belong to NGC 6866 and one to NGC 6811. The reddenings of these two clusters were adopted from Dutra & Bica (2000) for NGC 6866 and Glushkova et al. (1999) and Luo et al. (2009) for NGC 6811.

Values of $T_{\text{eff}}$ and $\log g$ were estimated from $c_0$ and $\beta$ using the data grid by Moon & Dworetsky (1985). The location of the seven stars with $uvby\beta$ photometry in the $c_0$, $\beta$ diagram is shown in Fig. 1. Typical photometric errors (0.015 and 0.03 mag in $b$, $y$, $c$, $\beta$) are in good agreement, with all the differences less than 3$\sigma$. Only KIC 05724440 (HD 187234) shows a difference in temperature close to the edge of this limit. We discuss this object in Section 3.3.

An additional photometric estimate of $T_{\text{eff}}$ can be obtained from the calibrations by Masana et al. (2006). These are based on the $(V-K)_0$ colour as well as on $\log g$ and $[Fe/H]$. The $V$ and $K$ band were taken from the SIMBAD and 2MASS catalogues, respectively. For $\log g$ we use the value from our spectroscopy. For the metallicity, following Bruntt et al. (2008), we adopted $[Fe/H] = -0.2 \pm 0.2$. This arbitrary value has only a small impact on the results because varying $[Fe/H]$ by $2\sigma$ gives an error of only 40 K in $T_{\text{eff}}$. To de-redden the observed $(V-K)$ colours we adopted the reddening reported in Table 1, using the relation $E(V-K) = 3.8\ E(b-y)$ (Cardelli et al. 1989) for the stars with Strömgren photometry, and $E(V-K) = 2.8\ E(B-V)$ for the other stars. The resulting $T_{\text{eff}}$ and the relative errors are reported in Table 2 (column 5). In general, there is
Table 2. Comparison of fundamental parameters obtained from spectroscopy and photometry, columns (2)-(6). In column (2) we report the Equivalent Spectral Type, i.e., the spectral type assigned to the stars by comparing the spectroscopic $T_{\text{eff}}$ with the table in Schmidt-Kaler (1982).

Figure 1. Location of the seven stars with $uvby\beta$ photometry in the $\beta - c_0$ diagram. The grid shows loci of constant $T_{\text{eff}}$ and $\log g$ (Moon 1985).

Table 3. Parameters from spectroscopy: $T_{\text{eff}}$, $\log g$ and rotational velocities.

We determined $T_{\text{eff}}$ and $\log g$ of the stars by minimizing the difference between the observed and the synthetic H$\beta$ profiles. For the goodness-of-fit parameter we used $\chi^2$ defined as

$$\chi^2 = \frac{1}{N} \sum \left( \frac{I_{\text{obs}} - I_{\text{th}}}{\delta I_{\text{obs}}} \right)^2$$

accessible via http://archive.stsci.edu/kepler/kepler_fov/search.php

© 2002 RAS, MNRAS 000, 1–12
where $N$ is the total number of points, $I_{\text{obs}}$ and $I_{\text{th}}$ are the intensities of the observed and computed profiles, respectively, and $\Delta I_{\text{obs}}$ is the photon noise. The errors have been estimated from the variation in the parameters required to increase $\chi^2$ by one. As starting values of $T_{\text{eff}}$ and $\log g$, we used $T_{\text{eff}}$ and $\log g$ derived from the photometry, as described in the previous section. At the same time, we determined the projected rotational velocity by matching the Mg $\text{II} \lambda4481$ Å profile with a synthetic profile. The synthetic profiles are computed with SYNTH (Kurucz & Avrett 1981) on the basis of ATLAS9 (Kurucz 1993a) LTE atmosphere models. All models are calculated using the solar opacity distribution function (ODF), solar metallicity and a microturbulence velocity of $\xi = 2\, \text{km}\,\text{s}^{-1}$. The atomic parameters for the spectral lines were taken from Kurucz & Bell (1995).

The derived values of $T_{\text{eff}}$, $\log g$ and $v\sin i$ are reported in Table 2 (columns 4, 9, and 3, respectively). The table also shows the equivalent spectral types and luminosity classes derived by comparing these values of $T_{\text{eff}}$ and $\log g$ with the tables in Schmidt-Kaler (1982). In Fig. 2, we show the spectra in three different wavelength ranges for two stars observed with both telescopes. The following lines are plotted: Mg $\text{II} \lambda4481$, Mg $\text{I} \lambda5167$, 5172 Å and the 5183-Å triplet, and H$\beta$. The Mg $\text{I}$ triplet was also used to check the derived values of $\log g$ for the coolest stars.

### 3.3 Comparison between astrophysical parameters derived by different methods

For the 15 stars with spectral types available in the literature (see column 6 of Table 1) we can compare these values with those derived in the present paper (column 2 of Table 2). For seven stars there is agreement. For the three stars classified as metallic-lined (Am stars) by Abt (1984), our inferred spectral type agrees with that from Balmer lines derived by this author on the basis of 1 Å resolution spectra. For the remaining five stars, the discrepancy is large, with differences of more than three or four spectral sub-types. This is not surprising because the nature of several classifications in the literature is uncertain or based on photometry. For these stars we adopt the values from our spectroscopic analysis.

The only high-resolution study in the literature is by Nordstrom et al. (1997) for the star KIC 07798339 (HD 173109). These authors analysed echelle spectra in the narrow wavelength range $5165.77 - 5211.25$ Å to obtain $T_{\text{eff}} = 7000$ K, $\log g = 3.5$ and $v\sin i = 15.4\, \text{km}\,\text{s}^{-1}$ (no errors available). The difference of 300 K in $T_{\text{eff}}$ is not significant within the errors.

6 KIC 05296877 (HAT 199-27597) and the three objects in NGC 6866 have no spectral type known before.
Comparison of Figure 3. G. Catanzaro et al. V photometrically via IRFM (top panel), (the sake of clarity, the literature (i.e. more precise reddening estimate). Note that for refer to stars for which Strömgren photometry is available in the able (see section 6 and Table 5). Symbols surrounded by circles represent variables classified as pure δ Sct, pure γ Dor, and hybrids, respectively; the cross shows the candidate W Uma variable (see section 6 and Table 5). Symbols surrounded by circles refer to stars for which Strömgren photometry is available in the literature (i.e. more precise reddening estimate). Note that for the sake of clarity, the T_eff of the three stars in NGC 6866 have been shifted by ±25 K. Note also that the star KIC 08583770 (HD 189177) is not visible in the figure because it lies outside the boundaries of the plots.

Figure 3. Comparison of T_eff obtained spectroscopically and photometrically via IRFM (top panel), (V - K) calibration, KIC. Inspection of Fig. 3, which illustrates such a comparison, shows a good agreement between T_eff(KIC) and log T_eff (middle panel). Filled circles, pentagons and open circles represent variables classified as pure δ Sct, pure γ Dor, and hybrids, respectively; the cross shows the candidate W Uma variable (see section 6 and Table 5). Symbols surrounded by circles represent variables classified as pure δ Sct, pure γ Dor, and hybrids, respectively; the cross shows the candidate W Uma variable (see section 6 and Table 5). Symbols surrounded by circles refer to stars for which Strömgren photometry is available in the literature (i.e. more precise reddening estimate). Note that for the sake of clarity, the T_eff of the three stars in NGC 6866 have been shifted by ±25 K. Note also that the star KIC 08583770 (HD 189177) is not visible in the figure because it lies outside the boundaries of the plots.

Figure 4. HR diagram for the nineteen stars investigated in this paper. Symbols are as in Fig. 3. Note that the T_eff of KIC 05965837 (HAT199-00623) was artificially lowered by 25 K to avoid a complete overlap with the star KIC 04570326 (HAT199-01905). The black solid line is the ZAMS from Pickles (1998); the blue solid lines show the δ Sct instability strip by Breger & Pamyatnykh (1998); the blue dashed and dotted lines show the empirical and theoretical red edge of the γ Dor instability strip by Handler & Shobbrook (2002) and Warner et al. (2003), respectively. and the log g and \( v \sin i \) values are in good agreement with our results.

It is useful to compare the values of T_eff derived spectroscopically and photometrically for those obtained via photometric methods (IRFM, (V - K) calibration, KIC). Inspection of Fig. 3, which illustrates such a comparison, shows a general good agreement among all these values. Quantitatively, a weighted mean of such differences gives: \( T_{\text{eff}}^{\text{spec}} - T_{\text{IRFM}}^{\text{spec}} = 200 \pm 200; T_{\text{eff}}^{\text{spec}} - T_{\text{V-K}}^{\text{spec}} = 140 \pm 200; T_{\text{eff}}^{\text{spec}} - T_{\text{eff}}^{\text{KIC}} = 50 \pm 300 \), non significant to the 1σ level. Similarly a very good agreement is found between \( T_{\text{eff}}^{\text{spec}} \) and \( T_{\text{eff}} \) estimated through \( uvby \) photometry (see Table 2). However there are two exceptions to this trend: KIC 05724440 (HD 187234) - This star shows a large difference between the spectroscopic T_eff and that estimated from \( uvby \) photometry (800 ± 300 K). Although this difference is not statistically significant (≈ 2.9σ), it deserves some comments. Indeed, there is no a clear explanation for such a large difference. The Loiano and INAF - OACT spectra give exactly the same values for T_eff and log g, suggesting that there could be a problem with the photometry. The \( uvby \) values reported for this star by Hauck & Mermillod (1998) are the average of the measurements by Olsen (1983) and Jordi et al. (1996), while the \( \beta \) value, on which the T_eff depends, was measured only by the latter authors. The two quoted \( uvby \) values are slightly discrepant, but the difference is not large enough to change significantly the derived value of log g.

We also considered the possibility that a close companion is affecting the photometric measurements. We visually inspected both POSS II and 2MASS images of KIC 05724440 (HD 187234), where the star appears to be isolated in the near infrared. In the optical it is surrounded by a few very close faint stars whose contribution can hardly be considered significant. By using the calibration by Masana et al. (2006), the discrepancy is reduced to only 350 K, reinforcing our suspicion that there is something wrong with the \( uvby \) photometry of this star.

KIC 08583770 (HD 189177) - The T_eff=9000 ± 200 K derived spectroscopically for this star is more than 3σ larger than the values derived from photometry, which cluster around 7700 K. This discrepancy can naturally be explained in terms of a visual binary, with a companion star dimmer by 3 mag at a distance of 0.9 arcsec. Even if nothing is known about the companion, due to the small separation, it is likely that the photometric values are affected by the secondary star flux. In particular, if the secondary star were a red object, this could justify the low temperature derived from the (V - K) color. On the contrary, in this case our T_eff estimate would not be affected because it is measured using the Hβ line.

4 THE HR AND log g – log T_eff DIAGRAMS

The stellar parameters log g and log T_eff determined in the previous section allow us to estimate the luminosity of the investigated objects by interpolating the tables by Schmidt-Kaler (1982). The result is reported in Table 3. Note that the
errors on the luminosity were evaluated through the same tables by taking into account the errors on log g and log $T_\text{eff}$. Figure 4 shows the HR diagram for the nineteen stars studied in this work, in comparison with the zero-age main sequence (ZAMS) (Pickles 1998), the observed instability strip for $\delta$ Sct stars (Breger & Pamyatnykh 1998) as well as the empirical and theoretical red edge of the $\gamma$ Dor instability strip (Handler & Shobbrook 2002; Warner et al. 2003). We note that the pulsating variables (see Section 6) are in the expected position, i.e. inside the instability strip, except for KIC 08583770 (HD 189177) and KIC 05296877 (HAT 199-27597) which are hotter and cooler than the instability strip, respectively. The former was discussed in the previous section, the latter is not a pulsating star (see Section 6).

We can use the values of log g and log $T_\text{eff}$ to estimate the mass of the target stars. For this purpose we used the evolutionary tracks in the BaSTI database which are based on the FRANCEC evolutionary code (Chieffi & Straniero 1989). We retrieved tracks with both canonical and non-canonical (i.e. with convective overshooting: $\Delta_{OV} = 0.2H_p$) physics in the mass range $1 - 6 M_\odot$ with $[M/H] = 0.058$, $Z = 0.0198$, $Y = 0.273$, and mixing length = 1.913 (Pietrinferni et al. 2004). In Fig. 5 we show the log g – log $T_\text{eff}$ diagram. The left and right panels in the figure show canonical and non-canonical tracks, respectively. The resulting masses for the two cases (listed in Table 3) are very similar and agree well within 1σ. On other hand, $\delta$ Sct stars are typically fast-rotating objects, and the rotation effects on the structure and evolution might modify the estimates of global parameters of the stars (see e.g. Goupil et al. 2005; Suárez et al. 2005; Fox Machado et al. 2006). To verify if this effect is important in our case, we considered a typical case for a star with mass 1.7-1.8 $M_\odot$. According to Suárez et al. (2005),
Table 4. Comparison between the luminosity derived from present spectroscopy and Schmidt-Kaler (1982) tables and the one obtained from the HIPPARCOS parallaxes or Cluster distance (see text).

Even in case of \( v \sin i=150-200 \) km/s, the effect on the mass estimate from the HR diagram is of few %, well within the uncertainty due to the errors on the empirical estimates of luminosity and effective temperature (see table 3).

5 CHECKS OF THE RESULTS BY MEANS OF PARALLAXES AND CLUSTER STARS

We used the parallaxes measured by the HIPPARCOS satellite (Perryman et al. 1997) to verify the luminosities derived in the present work. We also estimated independently the luminosity of cluster stars by adopting the distances found in the literature obtained through e.g. isochrone fitting.

Only four stars in our sample are sufficiently bright for inclusion in the HIPPARCOS parallax catalogue. These are listed in Table 4 together with the parallaxes from the van Leeuwen (2007) revised catalogue. To derive the luminosity we used the \( V \) and \( E(B-V) \) values listed in Table 4 as well as the bolometric correction as a function of spectral type from Pickles (1998). The resulting luminosities and errors are listed in Table 4 where our spectroscopic results are also shown for comparison purposes. An inspection of the table reveals that there is agreement within the errors. The only obvious discrepancy is found for the star KIC 03429637 (HD 178875). The difference in luminosity is \( \approx 2 \sigma \), and deserves some discussion. We did not find any significant difference between the spectroscopic and the photometric estimates of \( T_{\text{eff}} \) for this star. Furthermore, the HIPPARCOS parallax (van Leeuwen 2007) is very small relative to the parallax estimated from its spectral type and apparent magnitude. In our opinion, KIC 03429637 (HD 178875) is very likely a double star (Dominquet & Nys 1994). The binary nature can significantly affect the estimated luminosity, colour, and \( T_{\text{eff}} \). As mentioned in Section 3, our spectroscopic determination of \( T_{\text{eff}} \) is in agreement with that derived by Abt (1984).

As for cluster stars, we have to estimate the distances to the host clusters NGC 6866 and NGC 6811 first.

NGC 6866: as reported by Molenda-Żakowicz (2009), both the distance modulus and \( E(B-V) \) vary significantly from author to author. Here we decided to assume a distance \( D=1200 \pm 120 \) pc as in Molenda-Żakowicz (2009) (no error on distance is available in the literature, we assumed conservatively an uncertainty of 10%). As for the reddening we adopted \( E(B-V)=0.12 \pm 0.02 \), according to Dutra & Bica (2000) who made a study of the foreground and background dust in the direction of the cluster. The resulting luminosities for the three variables in NGC 6866 are shown in Table 4 in comparison with our estimates. The agreement is good within the errors.

NGC 6811: distance modulus and \( E(B-V) \) of this cluster were measured by Glushkova et al. (1999) and Luo et al. (2009). They found \( DM=10.42 \pm 0.03 \), \( E(B-V)=0.12 \pm 0.02 \), and \( DM=10.59 \pm 0.09 \), \( E(B-V)=0.12 \pm 0.05 \), respectively. To estimate the distance, we made a weighted mean of these results, obtaining \( D=1030 \pm 50 \) pc. Then, we calculated the luminosity for the star KIC 09655114 (NGC6811-RH35) which is reported in the last row of Table 4. Again, we note the good agreement within the errors with the spectroscopic result.

6 KEPLER OBSERVATIONS

Information on Kepler observations for the stars studied here is given in Table 5. For 12 out of 19 stars short cadence observations are available. From these data we calculated the periodograms shown in Fig. 6, by using a custom software based on a combination of FFT and normal periodogram. We note that practically all stars show peaks in both the low-frequency (\( \gamma \) Dor; \( g \) mode) and high-frequency (\( \delta \) Sct; \( p \) mode) regions. In this sense, practically all \( \delta \) Sct stars observed by Kepler are hybrids. This is a surprising finding which has been discussed in Grigahcène et al. (2010).

To make a distinction, we followed the classification scheme proposed by latter author. We visually classified the stars as \( \delta \) Sct if most of the peaks are in the \( \delta \) Sct region and as \( \delta \) Sct-\( \gamma \) Dor if most of the peaks are in the \( \delta \) Sct region but with a significant contribution from the \( \gamma \) Dor region. The frequency \( 5 \nu/d \) was taken as the boundary between the two regions. Following similar arguments, we classify a star as \( \gamma \) Dor or \( \gamma \) Dor-\( \delta \) Sct. There appears to be physical significance to such a scheme, as discussed by Grigahcène et al. (2010).

We applied these classification criteria to the stars of this study, and classified six targets as \( \delta \) Sct stars, five stars as \( \delta \) Sct-\( \gamma \) Dor hybrids, four stars as \( \gamma \) Dor-\( \delta \) Sct hybrids, and three stars as pure \( \gamma \) Dor pulsators (see also Table 5). Below we discuss the targets that show particularities in their periodogram (Fig. 6).

KIC 03429637 (HD 178875): As noted above, this star shows a \( \approx 2 \sigma \) difference between the luminosity values derived from the HIPPARCOS parallax and from spectroscopy (see Table 4). Binarity is a possible explanation for this discrepancy. The frequency spectrum shows two dominant peaks near 10 and 12 d-1. A model in terms of \( \delta \) Sct pulsations, rotation and/or binarity needs to be investigated.
Physical parameters of Kepler target

Figure 6. Periodograms of stars of Table 1. The precision in amplitude of the peaks in these periodograms is typically in the range of $1 - 10 \mu\text{mag}$.

**KIC 05296877 (HAT 199-27597):** This star is the coolest star in the sample and lies outside the instability strip. The periodogram shows a single strong peak at $f = 5.302 \text{c/d}$. KIC 5296877 is probably a contact binary with an orbital period of $2/f = 0.38 \text{d}$. The late spectral type of F4.5IV and the large value $v \sin i = 200 \text{km s}^{-1}$ suggest that it is a W UMa star.

**KIC 05724440 (HD187234):** A large difference is detected between the values of $T_{\text{Spec}}^{\text{eff}}$ and $T_{\text{uvby}}^{\text{eff}}$ (Section 3.3). The frequency spectrum of KIC 5724440 seems to show a $\delta$ Sct behaviour, with no particular abnormalities, which might confirm the suspicion that there is an error in the photometry of this star.

**KIC 07119530 (HD 183787):** This star has been classified as pure $\gamma$ Dor as the frequencies are predominantly in the $\gamma$ Dor range and those in the $\delta$ Sct region have low amplitude. However the star lies in the middle of the $\delta$ Sct instability strip. All the temperature indicators adopted in this paper agree very well with each other and indicate a $T_{\text{eff}} > 7500 \text{K}$, i.e. a bit too hot for a pure $\gamma$ Dor variable. We conclude that the variability classification of this star is uncertain since it could be a $\gamma$ Dor – $\delta$ Sct Hybrid.

**KIC 08583770 (HD 189177):** This star is the hottest star in the group, and lies outside the instability strip (see Fig 5). The periodogram shows significant power at very low frequency. The light curve of KIC 08583770 is presented in...

7 SUMMARY
We presented a spectroscopic analysis of 19 candidate δ  Sct variables observed by
Kepler both in long and short cadence mode. The analysis is based on medium- to high-resolution
spectra obtained at the Loiano and INAF - OACT observatories. For each star we derived Teff, log g and vsin i by
matching the observed spectra with synthetic spectra computed from the SYNTEH code (Kurucz & Avrett 1981) and
using the LTE atmospheric models calculated by ATLAS9 (Kurucz 1993a). The typical errors are about 200 K, 0.2 dex,
and 10 km s$^{-1}$ for Teff, log g, and vsin i, respectively. Equivalent spectral types and luminosity classes were also derived.
The luminosities of the stars were obtained using the tables of Schmidt-Kaler (1982).

For ten stars we used Strömgren photometry from the literature to estimate the reddening. For seven stars for
which β photometry was also available, Teff and log g could be obtained for comparison with our spectroscopic values.
In addition, V - K colours, the IFRM method and values listed in the KIC were used to obtain independent esti-
mates of Teff. We find a general good agreement between photometric and spectroscopic results, with the exception
of KIC 08583770 (HD 189177), which is a close visual binary. Four stars with significant parallaxes and four clus-
ter member objects were used to check our estimate of the luminosities. We obtain consistent results for all the stars,
with the exception of KIC 03429637 (HD 178875), which is a wide binary and may have an erroneous parallax determina-
tion. Moreover, for KIC05724440 (HD 187234) we suspect a problem with the uvbyβ photometry, since Teff derived from
the V - K index is in agreement with our estimate within the errors.

Finally, we present the periodograms for the 19 investiga-
ted stars, based on the Kepler satellite photometry. These beautiful data allowed us to classify the type of variability of
each star, including KIC05296877, which is a W Uma®
candidate. As a result, we find six pure δ  Sct, 3 pure γ  Dor and
nine hybrid pulsators. This classification is consistent with
the derived physical parameters and their position in the
HR diagram. As already noted by Grigahc`ene et al. (2010),
we were surprised by the large number of hybrid pulsators.
An asteroseismic study of these objects will have a strong
impact on our knowledge of the evolution and internal struc-
ture of A/F stars. A more in depth study of the pulsational

8 W Uma stars belong to a class of eclipsing binary variable star. These stars are close binaries, whose surfaces are in contact with
one another. They are termed contact binaries because the two stars touch and they essentially share material in their outer layer.
behaviour of the 18 pulsators is out of the scope of this paper, and will be presented in a forthcoming paper.

The stellar parameter estimates for the 18 investigated pulsating stars, presented in this work, will be a fundamental starting point for building proper asteroseismic models aimed at interpreting the frequency spectra extracted from the exceptionally good *Kepler* data.
